Abstract

The aim of this study was to determine the relationship between glucose, insulin, non-esterified fatty acid (NEFA) and indices of insulin resistance in the dry period (DP) and early lactation (EL). The importance of this study was in determining the relation between insulin sensitivity in DP and insulin resistance in EL. A total of 30 normally fed Holstein-Friesian cows with a high body condition score (> 3.75) were included in the study. Blood samples were collected in DP (weeks 5–7 ante partum) and EL (weeks 1–2 post partum). Cows in EL showed higher insulin resistance in comparison to DP due to a lower concentration of glucose and insulin, higher concentration of NEFA, lower value of revised quantitative insulin sensitivity check index and higher values of glucose:insulin and NEFA:insulin ratios (lower pancreas responsiveness to glucose and antilipolytic effect of insulin). Higher concentrations of insulin and glucose in the DP lead to a decrease in their concentrations and an increase in glucose:insulin and NEFA:insulin ratios in the EL. The revised quantitative insulin sensitivity check index in DP negatively correlates with the same index in EL, while positively correlating with the NEFA and NEFA:insulin ratio in EL. The EL revised quantitative insulin sensitivity check index value was influenced by dynamic changes (DP minus EL) in the insulin, NEFA, and glucose concentrations. The relationship between the indicators shows that higher insulin sensitivity in the DP increases resistance in EL in normally fed obese dairy cows.

Insulin sensitivity, periparturient period, energy balance, cattle

The period of lactation greatly affects the energy balance and insulin resistance in dairy cows. Insulin sensitivity/resistance is the principal mechanism for adapting the carbohydrate and lipid metabolism to lactation by directing glucose to the mammary gland and using adipose tissue to meet the energy requirements (De Koster and Opsomer 2013). Insulin resistance involves a decrease in insulin responsiveness, i.e. pancreatic beta-cell function, and/or insulin sensitivity, i.e. glucose entry into tissues through the action of insulin (Hayirli 2006).

In an experiment involving the use of insulin tolerance tests during 670 days of lactation, insulin resistance in the adipose tissue was found to change with the advance of lactation, creating favourable conditions for body fat deposition (Marett et al. 2017). Insulin has been proven to exert a lipogenic effect (Baumgard et al. 2016), which can lead to an increase in body fat reserves. Substantial body fat reserves in the dry period (DP) predispose cows to a significant decrease in the body condition score (BCS) after calving, increasing the overall lipid mobilization (Šamanc et al. 2015; Chapel et al. 2017). Increased lipid mobilization affects the insulin-regulated metabolism of carbohydrates and lipids, and reduces food intake, which can further aggravate the state of negative energy balance in early lactation.
and even compromise the health of cows (Janovick and Drackley 2010; Salin et al. 2012). In the close-up period, food intake restrictions reduce lipid mobilization and increase insulin sensitivity (Vailati-Riboni et al. 2017). A negative energy balance in EL is characterized by decreased glucose and insulin concentrations, and the heightened insulin resistance in adipose tissue resulting in lipolysis and elevated non-esterified fatty acid (NEFA) levels. In addition to the BCS, glucose and insulin concentrations increase from the peak of lactation to the DP, whereas the magnitude of insulin resistance and lipolysis decreases (Allen and Piantoni 2014). During EL, the glucose supply is for the most part used to meet the glucose requirements of milk production as the glucose transporters (GLUT) in the mammary gland are insulin-independent. Conversely, adipose tissue is insulin-dependent, and thus a decrease in insulin concentrations causes elevated NEFA concentrations necessary for the energy requirements of the organism (Duehlmeier et al. 2007; Zhao and Keating 2007; Baumgard and Rhoads 2013).

The aim of this study was to examine whether the heightened insulin sensitivity expected in dairy cows amid the far-off DP leads to a compensatory increase in insulin resistance after parturition by analyzing the relationship between changes in the insulin, glucose, NEFA and Revised Quantitative Insulin Sensitivity Check Index (RQUICKI) values in the DP and EL.

### Materials and Methods

#### Cows and management

A total of 30 Holstein-Friesian cows in the second and third lactation, with a milk yield of 7500 ± 950 l and no clinical signs of health impairment, were enrolled in the study. Raised in a free-range system, all the cows were amid the far-off DP (days -40 ± 7 relative to calving) and with a BCS >3.75. They were fed total mixed rations (TMRs), adequately meeting the cows’ nutritional requirements. The late-gestation cows received a diet of 1.5 kg grass hay, 0.60 kg wheat straw, 10 kg corn silage (33% dry matter - DM), 2.50 kg alfalfa haylage (51.79% DM), 0.98 kg corn grain, 0.50 kg soybean grits, 1.10 kg soybean meal (44% N) and 0.50 kg wheat flour. The EL cows received a diet of 3.43 kg alfalfa hay, 9.50 kg corn silage (44% DM), 5.0 kg corn grain, 1.50 kg barley grain, 1.30 kg soybean grits, 1.13 kg soybean meal (44% N), 1.30 kg wheat flour and 1.82 kg sugar beet pulp.

#### Blood sampling

Blood samples were collected by coccygeal venipuncture before the morning feeding to minimize the postprandial effect on metabolic values. Blood samples were taken in weeks 5 to 7 ante partum (DP) and weeks 1 to 2 post partum (EL). The samples for biochemical analysis were collected in 10 ml BD Vacutainer® SST II Advance tubes (BD Plymoth, UK), containing silica to activate the specimen clotting and a gel which forms a barrier between the clot and the serum after centrifugation. The collection tubes were centrifuged at $3,500 \times g$ for 10 min in order to completely separate the serum from the clot. The collected blood samples immediately underwent laboratory analysis.

#### Blood sample analysis

Concentrations of glucose, insulin and NEFA were determined in the blood samples collected during the DP. The glucose and NEFA levels were measured using the spectrophotometric Randox (Crumlin, UK) and Biosystems (Barcelona, Spain) kits, and the values obtained were read using a Rayto biochemistry analyzer. The insulin concentrations were determined using the Sandwich enzyme-linked immunosorbent assay (ELISA) kit Cusabio (Wuhan, China), and the insulin values were read using an ELISA reader Rayto (Shenzen, China).

#### Calculation of the indices

The testing for insulin resistance in this study was based on the RQUICKI index ($\text{RQUICKI} = \frac{1}{\log(\text{glucose mg/dl}) + \log(\text{insulin \mu U/ml}) + \log(\text{NEFA mmol/l})})$ (Holtenius and Holtenius 2007). The NEFA:insulin and glucose:insulin ratios were calculated as a unit of NEFA and glucose per one unit of insulin, representing the insulin response to the glucose and insulin antilipolytic effect.

#### Data analysis

Differences in the insulin, glucose, NEFA and RQUICKI values during the DP and EL were determined using paired t-tests. The relationship between the obtained values was examined using correlation and regression between the insulin, glucose, NEFA and RQUICKI values in the DP and the period after parturition. A multiple
regression equation was used to explicate the effect of dynamic changes in the insulin, glucose and NEFA values on the RQUICKI values after parturition.

**Results**

Cows in EL showed higher insulin resistance in comparison to DP due to lower concentration of glucose and insulin, a higher concentration of NEFA, a lower value of RQUICKI and higher values of glucose:insulin and NEFA:insulin ratios (lower pancreas responses to glucose and the antilipolytic effect of insulin). These values were determined in the DP vs EL: glucose 3.4 ± 0.35 vs 2.42 ± 0.42 mmol/l; insulin 17.27 ± 3.02 vs 10.48 ± 2.33 µU/l; NEFA 0.19 ± 0.08 vs 0.6 ± 0.18 mmol/l; RQUICKI 0.44 ± 0.02 vs 0.41 ± 0.03; glucose:insulin ratio 3.67 ± 0.76:4.26 ± 0.72; and NEFA:insulin ratio 0.012 ± 0.009:0.061 ± 0.03. The results of paired t-tests indicate a significant difference between the values obtained in the DP and the EL (Table 1).

Higher insulin sensitivity in the DP increases resistance in the EL due to the following factors: a) higher concentrations of insulin and glucose in the DP lead to a decrease in the their concentrations and an increase in the glucose:insulin and NEFA:insulin ratios in the EL; b) the RQUICKI in the DP negatively correlates with the same index in the EL while positively correlating with the NEFA and NEFA:insulin ratio in the EL. Correlations and regressions are presented at Table 2 and Figs 1a-d, 2a-d, 3a-d.

The RQUICKI value in the EL was influenced by dynamic changes (DP minus EL) of the insulin, NEFA, and glucose concentrations. The change in NEFA showed the highest contribution to the RQUICKI value (highest t-value). Results are presented at Table 3 and Fig. 4.

Discussion

An inverse correlation was found between the values of insulin, glucose, NEFA and RQUICKI in the DP and EL. The obtained results can be accounted for by the metabolic status of cows in the DP and EL. In mid- and late lactation, the energy requirements of the cow’s organism are fully met. Moreover, the energy supplies often exceed the requirements,
and thereby the surplus of energy is stored in body depots in the form of glycogen, fat, and protein (Grummer 2008). A positive energy balance is characterized by increased hepatic gluconeogenesis, decreased peripheral glucose uptake, constant or reduced acetate use, moderate fatty acid mobilization from body depots, and increased fatty acid utilization in the peripheral tissues (Bell 1995). Low insulin concentrations after parturition, secreted by pancreatic beta-cells, are associated with the decreased expression of insulin-dependent GLUT-4 transporters. Accordingly, the glucose uptake in muscle and adipose tissues is diminished in order to supply insulin-independent tissues with glucose (mammary gland). Such results were reported by Duehlmeier et al. (2007) and Zhao and Keating (2007).

Elevated insulin concentrations are associated with a positive energy balance (Holtenius et al. 2003; De Koster et al. 2015). An increase in insulinaemia can result as a consequence of insulin resistance (Ahrén and Pacini 2004). However, our results show that the DP insulin:glucose and insulin:NEFA ratios are lower than those obtained in the postpartum EL period, which is indicative of enhanced insulin sensitivity. A significant decrease in the insulin and glucose concentrations was reported in EL, and a positive correlation was found between the insulin and glucose values after parturition. A decrease in feed intake in the periparturient period lowers glucose concentrations (Bjerre-Harpøth et al. 2012). Oral feed (glucose) intake acts as a much stronger stimulus to insulin secretion than intravenous glucose administration, as glucose regulates insulin gene expression (Baumagard et al. 2016). All the aforementioned considerations confirm a significant correlation between insulin and glucose values in the postpartum period.

A significantly negative correlation was found between insulin and NEFA values in the DP (Table 2) compared to the non-significant correlation found in the postpartum period. Elevated NEFA concentrations decrease glucose clearance due to lower insulin sensitivity in tissues, changes in insulin secretion and changes in insulin clearance (Salin et al. 2012; Schoenberg et al. 2012). A laboratory mouse model was used to show adverse effects of NEFAs on pancreatic beta-cells (Meadler et al. 2001). Pires et al. (2007) demonstrated a relationship between NEFA concentrations and insulin resistance in cows by induced hyperlipidaemia, infusing tallow emulsion.

The RQUICKI is an indirect indicator of insulin sensitivity in cows. This index shows lower values in EL compared to the DP (Cincović et al. 2014), and a significant relationship with the metabolic and endocrinological indicators in EL (Cincović et al. 2017). A negative correlation was found between the RQUICKI values and the insulin, glucose, and NEFA values in the EL period, compared to a significant correlation between the RQUICKI and NEFA values in the DP period. A negative correlation between the RQUICKI and insulin values was also found by Locher et al. (2015). The RQUICKI index is an excellent indicator of the antilipolytic effect of insulin (Perseghin et al. 2001). Models examining high energy intake during the DP have demonstrated a decrease in the index of insulin sensitivity and an increase in insulin values in overfed/overconditioned cows compared to normally-fed cows, and no differences were found in the postpartum insulin sensitivity (or that it was even enhanced) (Rukkwamsuk et al. 1998; Locher et al. 2015; Salin et al. 2017). The RQUICKI index can only be used for the assessment of insulin resistance in cows with the same metabolic status (Schoenberg and Overton 2011). Therefore, it is rather difficult to make a direct comparison of our results with those reported elsewhere in the literature.

The obtained postpartum RQUICKI values were influenced by dynamic changes in the insulin, glucose and NEFA values in the periparturient period. Significant changes were recorded in the insulin and NEFA values compared to the changes in glycaemia (the t-value comparison), which confirms that the RQUICKI index was indicative of the antilipolytic effect of insulin in this study. The correlation between the obtained values suggests that changes in insulin secretion and lipid levels greatly affect the
insulin resistance in EL. The negative correlation determined between RQUICKI values in the DP and EL is influenced by the magnitude of change in lipolysis. Bossaert et al. (2008) reported a negative correlation between plasma NEFA values and the insulin area under the curve and peak values, without affecting the glucose values in postpartum cows.

In conclusion, the relationship between insulin, glucose, NEFA, RQUICKI, glucose to insulin and NEFA to insulin ratio in the DP and EL presented that higher insulin sensitivity in DP compensatory increases resistance in EL in normally-fed obese dairy cows. Analysis of the mentioned indicators during the DP in obese cows may be a practical tool for a prediction of insulin resistance in EL. These findings warrant further research.
